An Empirical Evaluation of Capital and Operational Expenditure Reductions in US Commercial Banking Through Permissioned Distributed Ledger Technology Implementation

Authors

Billy Elly, Goodness Ola, Deborah James

Date; November 24, 2026

Abstract

US commercial banks allocate approximately 14% of noninterest expenses to technology, yet the financial returns on permissioned distributed ledger technology (DLT) remain inadequately quantified outside vendor projections and limited pilot studies . This study addresses the research gap concerning the absence of a validated empirical framework for estimating capital expenditure (CapEx) and operational expenditure (OpEx) reductions attributable specifically to permissioned DLT deployment in US banking contexts. The purpose is to empirically evaluate the magnitude and determinants of cost reductions through a retrospective analysis of production DLT implementations and a prospective simulation of scaled deployment. The methodology combines fixed-effects panel regression on bank-level expense data (2016–2024) with a Monte Carlo simulation of DLT-enabled process transformations in settlement, reconciliation, and syndicated lending workflows. Key findings indicate an 89.4% accuracy in predicting OpEx reduction trajectories when controlling for bank size, existing technology infrastructure, and transaction volume, with mean operational savings of 23.7% in reconciliation functions and 18.2% in settlement processing. CapEx reductions averaged 14.1% over a five-year horizon, primarily through reduced middleware and integration expenditures. The main conclusion is that permissioned DLT delivers statistically significant but unevenly distributed cost benefits,

contingent upon organizational scale and process standardization. Practical implications include a replicable estimation model for bank administrators and a regulatory framework recommendation for FDIC guidance on tokenized deposit treatment.

Keywords: permissioned distributed ledger technology, commercial banking, operational expenditure, capital expenditure, tokenized deposits

1. Introduction

1.1 Background

The US commercial banking sector operates under persistent margin compression, with the industry efficiency ratio hovering near 60% and technology spending consuming an estimated 14% of noninterest expenses across the sector . This expenditure burden has intensified as banks confront modernization imperatives spanning digital infrastructure, cybersecurity, and regulatory compliance. Within this context, permissioned distributed ledger technology has emerged as a candidate infrastructure layer capable of restructuring core banking processes—particularly interbank settlement, trade finance, and syndicated lending—by replacing sequential, intermediary-dependent workflows with synchronized, cryptographically secured transaction records .

The technological maturation of permissioned DLT has accelerated markedly since 2023. SWIFT advanced its shared ledger initiative from design to MVP stage in 2026, involving more than 30 global financial institutions including JPMorgan, HSBC, and Bank of America, with the explicit objective of collapsing messaging and settlement into a single layer to achieve “drastically reduced reconciliation effort” . In the US domestic context, JPMorgan’s Kinexys platform and Citi Token Services have moved tokenized deposit capabilities from pilot to production for institutional clients . The Federal Reserve Bank of Dallas has articulated the operational logic of deposit tokens, noting that while tokenization accelerates front-end transfers, interbank obligations may continue to settle through existing infrastructures such as Fedwire, creating hybrid arrangements that require careful cost accounting .

Concurrently, empirical evidence on DLT’s cost impact has begun to accumulate. A 2025 study employing autoregressive distributed lag modeling on Federal Reserve FRED data (2010–2024) found that a 1% increase in syndicated loan volume on permissioned DLT platforms reduced the operating expense ratio by 0.147%, implying approximately 15% structural reduction in back-office burden for participating banks . A separate systematic review of digital technologies in banking reported that blockchain-enabled cross-border payment systems can eliminate up to 50% of transaction processing costs, with comprehensive digital transformation strategies improving cost-to-income ratios from 65–75% to 35–50% . However, these findings exhibit considerable

heterogeneity across institutional contexts, and no study has produced a validated predictive framework for estimating CapEx and OpEx reductions specific to US commercial banks considering permissioned DLT adoption.

1.2 Problem Statement

Despite growing pilot activity and favorable qualitative assessments, the empirical literature on permissioned DLT in banking suffers from three interrelated deficiencies. First, existing cost estimates are predominantly derived from vendor case studies or limited pilot environments that do not reflect production-scale operations. The Bank of Canada's Project Samara, for instance, documented operational efficiency gains from tokenized bond issuance on Hyperledger Fabric, but explicitly cautioned that these improvements were "partially offset by increased system complexity, liquidity costs, and gaps in the current regulatory framework," concluding that broader adoption will likely be slow . Such findings suggest that pilot-stage cost reductions may not generalize to full deployment.

Second, the literature lacks a disaggregated analysis distinguishing between capital expenditure reductions—arising from infrastructure consolidation, middleware elimination, and reduced integration costs—and operational expenditure reductions, which accrue from automated reconciliation, smart contract execution, and reduced manual intervention. The syndicated loan study by the FRED-based analysis represents a notable exception in quantifying OpEx effects, but it does not address CapEx implications . Similarly, the Dallas Fed's analysis of deposit token models describes operational mechanics but does not quantify expenditure outcomes .

Third, no study has developed and validated a predictive model that US bank administrators can employ ex ante to estimate the financial viability of permissioned DLT investment under their specific organizational parameters. The consequence is that adoption decisions proceed on the basis of vendor projections and peer emulation rather than empirically grounded estimation, exposing institutions to capital misallocation risk. This study addresses this gap by constructing and validating a predictive framework for CapEx and OpEx reduction estimation using both retrospective production data and simulation-based prospective analysis.

1.3 Objectives of the Study

General objective: To empirically evaluate the magnitude, determinants, and predictability of capital and operational expenditure reductions achievable through permissioned distributed ledger technology implementation in US commercial banking.

Specific objectives:

1. To quantify the differential effects of permissioned DLT deployment on capital expenditure versus operational expenditure across US commercial bank size cohorts.
2. To construct and validate a predictive model of DLT-attributable cost reduction incorporating bank-specific, transaction-specific, and implementation-specific predictors.

3. To assess the boundary conditions under which permissioned DLT cost benefits are realized or eroded, including regulatory uncertainty and interoperability constraints.

1.4 Research Questions

1. What is the magnitude and statistical significance of CapEx and OpEx reductions attributable to permissioned DLT implementation in US commercial banks, disaggregated by bank size and process domain?
2. What combination of organizational and implementation variables most accurately predicts the realization of DLT-attributable cost reductions, and with what predictive accuracy?
3. What implementation barriers and boundary conditions moderate the translation of DLT technical capabilities into realized financial savings?

1.5 Significance of the Study

For practitioners and bank administrators: The validated predictive framework provides a structured estimation tool for evaluating permissioned DLT investment proposals. Rather than relying on vendor assertions, administrators can input bank-specific parameters—asset size, existing middleware expenditure, transaction volumes, and process standardization levels—to generate empirically grounded CapEx and OpEx reduction projections with quantified confidence intervals.

For policymakers: The findings inform the ongoing regulatory deliberation regarding tokenized deposits. The FDIC has signaled forthcoming guidance on the regulatory status of tokenized deposits, and state supervisors have urged coordinated federal guidance before banks commit significant capital . This study's quantification of cost structures provides an evidentiary basis for calibrating regulatory requirements to actual operational realities rather than precautionary assumptions.

For academic literature: The study extends the empirical DLT cost literature beyond pilot-stage case studies by introducing a predictive modeling approach and by disaggregating CapEx from OpEx effects. It also contributes to the theoretical understanding of how institutional technologies interact with organizational scale and process standardization to produce heterogeneous outcomes.

For future researchers: The methodology and framework are designed for replication and extension to other institutional contexts, including community banks, credit unions, and non-US banking systems with differing regulatory architectures.

1.6 Scope and Limitations

This study analyzes US commercial banks with total assets exceeding $10 billion, a threshold selected to ensure adequate representation of institutions with both the operational scale to justify

permissioned DLT investment and sufficient public disclosure for empirical analysis. The time period spans 2016 through 2024 for retrospective analysis, with prospective simulation extending through 2029. Data sources include Federal Reserve FRED series, FDIC Call Report data, and publicly disclosed DLT implementation metrics from JPMorgan, Citi, and consortium participants.

The study excludes community banks below $10 billion in assets, non-bank financial institutions, and non-US banking systems. It does not assess revenue-side effects of DLT, nor does it evaluate customer-facing applications such as retail payments or wealth management. Key limitations include reliance on simulated data for certain CapEx components where bank-level disclosure is insufficient, the assumption of historical pattern stability under which cost relationships observed during the sample period persist into the forecast horizon, and the treatment of regulatory uncertainty as an exogenous constraint rather than an endogenously modeled variable.

2. Literature Review

2.1 Conceptual Review

Permissioned Distributed Ledger Technology: A permissioned DLT is a distributed ledger architecture in which access and validation rights are restricted to authorized participants, typically financial institutions or consortium members. Unlike public blockchains, permissioned networks do not require proof-of-work consensus; instead, they employ voting-based or Byzantine fault-tolerant consensus mechanisms among known validators. This architecture preserves the privacy and compliance boundaries essential to regulated banking while enabling synchronized state across participants .

Tokenized Deposits: A tokenized deposit is a digital representation of a commercial bank deposit that remains on the issuing bank's balance sheet and is redeemable at face value. Tokenized deposits differ from stablecoins in that they constitute direct claims on a regulated depository institution, preserving deposit insurance and Bank Secrecy Act compliance . The Dallas Fed distinguishes deposit tokens from stablecoins by their embeddedness in the regulated banking system and their issuance by institutions subject to prudential supervision .

Capital Expenditure: In the banking context, CapEx encompasses investments in physical and technological infrastructure with multi-year useful lives, including hardware, software licenses, systems integration, and implementation services. Permissioned DLT affects CapEx through consolidation of middleware layers, reduction in integration complexity, and substitution of proprietary messaging infrastructure with shared ledger protocols .

Operational Expenditure: OpEx comprises recurring costs of maintaining and operating banking infrastructure and personnel, including reconciliation labor, settlement processing,

compliance verification, and IT maintenance. DLT-attributable OpEx reductions arise from automated reconciliation through shared state, smart contract execution of previously manual processes, and elimination of redundant data entry and verification steps .

Efficiency Ratio: The ratio of noninterest expense to net operating revenue, a standard metric of bank operational efficiency. Reductions in this ratio indicate that a bank is generating more revenue per unit of operating cost, or equivalently, reducing costs relative to revenue.

2.2 Theoretical Framework

Transaction Cost Economics: Williamson's transaction cost framework provides the foundational logic for understanding DLT's economic impact. According to this theory, the choice between hierarchical (internal) and market-based coordination depends on transaction frequency, uncertainty, and asset specificity . Permissioned DLT alters this calculus by reducing uncertainty through immutable, auditable transaction records and by lowering the marginal cost of repeated transactions through smart contract automation. Processes previously internalized within bank hierarchies—such as reconciliation, verification, and settlement confirmation—can be restructured as shared, cryptographically validated operations across a consortium, effectively shifting coordination from hierarchical to network governance .

Prospect Theory: Bank administrators evaluating DLT investment face asymmetric perceptions of gain and loss. The potential cost savings represent uncertain gains, while the implementation expenditure and organizational disruption represent certain losses. Prospect theory predicts that decision-makers will weight certain losses more heavily than probabilistic gains, potentially explaining the observed sluggishness of DLT adoption despite favorable pilot evidence . This theoretical lens informs the study's attention to implementation barriers and the distinction between technical feasibility and organizational adoption.

Economies of Scale and Scope in Technology Adoption: Morningstar's analysis of technology-enabled banking transformation documents that the marginal cost of serving an additional customer on a digital platform is substantially lower than under brick-and-mortar architecture, and that technology expenses are most efficiently absorbed by large customer bases . This theory predicts that permissioned DLT cost benefits will be disproportionately realized by larger institutions, a hypothesis tested in the empirical analysis.

2.3 Empirical Review

Sabeena et al. (2025) examined blockchain-based banking infrastructure for securing financial transactions and reducing operational costs in the US context. Their analysis concluded that blockchain implementation in US banking operations produces measurable reductions in transaction processing costs and enhances security outcomes, though the study relied primarily on qualitative synthesis rather than bank-level econometric analysis. The authors did not disaggregate CapEx from OpEx effects, nor did they develop a predictive framework for estimating cost reductions under varying organizational parameters .

The FRED-based ARDL study (2025) provides the most rigorous existing quantification of DLT's OpEx impact. Using quarterly data from 2010 to 2024 and a dummy variable denoting production DLT implementation after 2016, the study found cointegration between syndicated loan volumes on DLT platforms and bank operating expense ratios, estimating a long-run elasticity of –0.147 and a short-run elasticity of –0.276 with a 47% quarterly correction rate . While methodologically robust, this study is limited to the syndicated lending domain and does not address CapEx, nor does it generate a predictive model for individual bank estimation.

The Bank of Canada's Project Samara (2026) tested a C$100 million tokenized bond issuance on Hyperledger Fabric with TD Bank and RBC, documenting operational efficiency gains and improved data integrity but also identifying "increased system complexity, liquidity costs, and gaps in the current regulatory framework" as offsetting factors. The project concluded that broader adoption will likely be slow due to integration challenges and limited appetite for core infrastructure changes . This finding underscores the importance of distinguishing between technical cost reduction potential and realized financial outcomes under organizational constraints.

The systematic review by Garuda (2026) synthesized evidence from Scopus, Web of Science, and IEEE Xplore publications (2020–2025) on digital technologies in banking cost optimization. The review reported that blockchain-enabled cross-border payment systems can eliminate up to 50% of transaction processing costs and that comprehensive digital transformation improves cost-to-income ratios from 65–75% to 35–50%. However, the review aggregated heterogeneous technologies and did not isolate permissioned DLT effects specifically .

SWIFT's 2026 shared ledger initiative provides industry-level evidence of the operational logic underlying DLT adoption. The initiative, involving JPMorgan, HSBC, BNP Paribas, Deutsche Bank, and Bank of America, is designed to collapse messaging and settlement into a single layer, yielding "drastically reduced reconciliation effort" and "better liquidity visibility" . While the initiative is not yet live, its architecture and participant composition signal that the largest US banks perceive material operational benefits sufficient to justify participation costs.

2.4 Research Gap

No validated predictive framework exists that empirically models the differential CapEx and OpEx reduction trajectories of permissioned DLT implementation across US commercial bank size cohorts, incorporating bank-specific and implementation-specific predictors with quantified predictive accuracy.

This gap is consequential because the existing literature provides either (a) domain-specific elasticities that cannot be generalized to overall bank expenditure , (b) pilot-stage qualitative assessments that do not reflect production-scale economics , or (c) aggregated technology impact estimates that confound DLT with other digital transformations . Bank administrators considering DLT investment lack a tool that translates their institution's specific characteristics into

empirically grounded cost reduction projections. This study fills that gap by constructing and validating such a framework.

3. Methodology

3.1 Research Design

The study employs a mixed-methods quantitative design combining retrospective panel data analysis with prospective Monte Carlo simulation. The retrospective component estimates historical relationships between permissioned DLT implementation and bank expenditure outcomes using fixed-effects panel regression on bank-level data from 2016 to 2024. The prospective component applies these estimated relationships to simulated bank profiles across parameter distributions to generate cost reduction projections under uncertainty. This design is appropriate because the limited number of production-scale DLT implementations in US banking precludes randomized controlled trial designs, while the available panel data permit credible identification of implementation effects through within-bank variation over time.

3.2 Study Area and Population

The target population comprises US commercial banks with total assets exceeding $10 billion as reported in FDIC Call Reports for the period 2016–2024. This threshold yields approximately 130 institutions, of which 23 have disclosed production-level permissioned DLT implementations in at least one business process domain (settlement, reconciliation, trade finance, or syndicated lending) during the sample period. The unit of analysis is the bank-year observation, yielding an unbalanced panel of approximately 950 observations after excluding missing data.

3.3 Sample Size and Sampling Technique

The sample consists of all 23 banks with disclosed production DLT implementations, plus a matched comparison group of 46 banks without DLT implementation, selected via propensity score matching on asset size, business model (commercial versus diversified), and pre-implementation efficiency ratio. The matched sample of 69 banks yields approximately 620 bank-year observations. Stratification is applied by asset size cohort: large ($250B+), mid-large ($100–250B), and regional ($10–100B). This sampling approach ensures adequate representation across size categories while controlling for selection bias in DLT adoption.

3.4 Data Collection Methods

Data sources include: (a) FDIC Call Reports for bank-level financial variables (noninterest expense, assets, revenue, efficiency ratio); (b) Federal Reserve FRED series for syndicated loan volumes and macroeconomic controls; (c) publicly disclosed DLT implementation

announcements and quarterly reports from JPMorgan, Citi, and consortium participants; and (d) industry benchmark data from Morningstar and S&P Global on technology spending ratios . The time period spans 2016–2024 for retrospective analysis.

Certain CapEx component data are simulated where bank-level disclosure is insufficient. Specifically, middleware expenditure and systems integration costs are not separately reported in Call Reports; these are estimated using industry ratio benchmarks derived from Morningstar's technology spending analysis and adjusted by bank size . Simulated values are flagged, and sensitivity analysis is conducted to assess the robustness of findings to simulation assumptions.

3.5 Research Instruments

Analysis is conducted in Python 3.11 using the following libraries: pandas and numpy for data manipulation; statsmodels for fixed-effects panel regression and diagnostic testing; linearmodels for panel data estimation with clustered standard errors; scipy for statistical inference; and matplotlib/seaborn for visualization. Preprocessing includes winsorization of expenditure ratios at the 1st and 99th percentiles to mitigate outlier influence, log transformation of size variables, and creation of a DLT implementation indicator variable based on disclosed production deployment dates. The ARDL bounds testing approach follows the methodology established in the syndicated loan literature .

3.6 Validity and Reliability

Content validity: The expenditure categories and DLT implementation definitions were reviewed against Federal Reserve and FDIC reporting frameworks to ensure alignment with regulatory concepts. The syndicated lending domain classifications follow those employed in the FRED-based study .

Predictive validity: The model's predictive accuracy is assessed through out-of-sample validation using a holdout period of 2023–2024 observations not employed in estimation. An accuracy threshold of 85% correct classification of above-versus-below median cost reduction is pre-specified as the criterion for predictive validity.

Inter-rater reliability: DLT implementation dates were coded by two independent reviewers from public disclosures; disagreements were resolved through consensus, with initial agreement of 91.3% (Cohen's $\kappa = 0.87$).

3.7 Data Analysis Techniques

The analysis proceeds in three stages. First, fixed-effects panel regression estimates the relationship between DLT implementation and expenditure outcomes:

$$ExpenseRatio_{it} = \alpha_i + \beta_1 DLT_{it} + \beta_2 Size_{it} + \beta_3 Revenue_{it} + \beta_4 Loans_{it} + \gamma_t + \epsilon_{it}$$

where $ExpenseRatio_{it}$ is the ratio of noninterest expense to assets for bank i in year t; DLT_{it} is an indicator for production implementation; $Size_{it}$ is log total assets; $Revenue_{it}$ and $Loans_{it}$ are controls; α_i are bank fixed effects; γ_t are year fixed effects; and standard errors are clustered at the bank level.

Second, the estimated coefficients are employed to generate predicted cost reduction trajectories for each bank in the simulation sample. Third, Monte Carlo simulation (10,000 iterations) samples from the empirical distribution of bank characteristics and model uncertainty to produce confidence intervals around projected CapEx and OpEx reductions.

Performance metrics include: (a) mean absolute percentage error (MAPE) for continuous predictions; (b) area under the receiver operating characteristic curve (AUC) for binary classification of above-median savings; and (c) out-of-sample R^2. Cross-validation employs 5-fold panel cross-validation with bank-level clustering to prevent information leakage across time periods within the same institution.

3.8 Ethical Considerations

This study utilizes de-identified, publicly available data from FDIC Call Reports, Federal Reserve economic data series, and corporate disclosures. No protected health information (PHI) or non-public personally identifiable information is accessed. The research is exempt from Institutional Review Board review under 45 CFR 46.104(d)(4) as analysis of publicly available de-identified data. All data sources are properly cited, and no confidential supervisory information is employed.

4. Results

4.1 Data Presentation

Table 1. Descriptive Statistics by DLT Implementation Status (2016–2024)

Indicator	DLT Implementers (n=23 banks, 207 obs)	Matched Non-Implementers (n=46 banks, 414 obs)
Total Assets ($B, mean, SD)	412.7 (386.2)	398.4 (371.8)

Indicator	DLT Implementers (n=23 banks, 207 obs)	Matched Non-Implementers (n=46 banks, 414 obs)
Noninterest Expense / Assets (%, mean, SD)	2.41 (0.38)	2.53 (0.41)
Efficiency Ratio (%, mean, SD)	58.2 (6.7)	61.4 (7.2)
Syndicated Loan Volume ($B, mean, SD)	84.3 (72.1)	79.6 (68.9)
Technology Spending / Noninterest Expense (%)	16.8 (3.2)	14.1 (2.8)
Years Since DLT Implementation (mean, SD)	3.8 (1.6)	—

Table 1 presents the descriptive statistics for the matched sample. DLT implementers exhibit marginally lower noninterest expense ratios and efficiency ratios in the post-implementation period, though the raw differences are confounded by selection effects and time trends. Technology spending as a share of noninterest expense is higher among implementers, consistent with the interpretation that DLT adoption occurs alongside broader technology modernization.

Table 2. Estimated DLT Effects on Expenditure Ratios (Fixed-Effects Panel Regression)

Dependent Variable	Coefficient on DLT Indicator	Std. Error	p-value	95% CI
Noninterest Expense / Assets	−0.127	0.041	0.002	[−0.208, −0.046]
Reconciliation Expense / Total OpEx	−0.237	0.052	<0.001	[−0.339, −0.135]

Dependent Variable	Coefficient on DLT Indicator	Std. Error	p-value	95% CI
Settlement Processing Expense / Total OpEx	−0.182	0.048	<0.001	[−0.276, −0.088]
CapEx / Total Assets (5-year average)	−0.141	0.039	0.001	[−0.218, −0.064]

Table 2 reports the core fixed-effects estimates. The DLT implementation indicator is associated with a 12.7 basis point reduction in the noninterest expense-to-assets ratio, a 23.7% reduction in reconciliation expense, an 18.2% reduction in settlement processing expense, and a 14.1% reduction in the five-year average CapEx ratio. All estimates are statistically significant at the 1% level.

4.2 Analysis of Results

Model performance. The predictive model incorporating bank size, pre-implementation efficiency ratio, technology spending intensity, and transaction volume achieved an out-of-sample classification accuracy of **89.4%** for predicting above-versus-below median OpEx reduction (AUC = 0.913). The out-of-sample R^2 for continuous OpEx reduction prediction was 0.71, and MAPE was 14.2%. For CapEx reduction prediction, accuracy was 84.7% (AUC = 0.871) with R^2 of 0.63. The 89.4% accuracy figure exceeds the pre-specified validity threshold of 85%.

Comparison against baseline. The static budget method—which assumes no change in expenditure ratios from pre-implementation levels—produces a MAPE of 28.6% for OpEx prediction and 31.2% for CapEx prediction. The DLT-informed model reduces prediction error by approximately half relative to this baseline. Compared to a simple time-trend extrapolation, the DLT model reduces OpEx MAPE from 19.8% to 14.2%.

Feature importance. The strongest predictors of realized OpEx reduction are, in order of standardized coefficient magnitude: (1) pre-implementation reconciliation expense intensity ($\beta = 0.41$); (2) syndicated loan volume ($\beta = 0.33$); (3) bank asset size ($\beta = 0.28$); (4) years since implementation ($\beta = 0.22$); and (5) technology spending intensity ($\beta = 0.16$). The positive coefficient on syndicated loan volume indicates that banks with higher volumes in DLT-enabled domains realize larger proportional savings, consistent with the economies of scale mechanism .

Statistical significance. The regression F-statistic for the full model is 18.42 ($p < 0.001$), and the within-R^2 is 0.34. Diagnostic tests confirm no evidence of serial correlation (Wooldridge test $p = 0.21$) and homoskedasticity-robust standard errors are employed throughout.

5. Discussion

5.1 Interpretation

Finding 1: DLT produces statistically significant but moderate OpEx reductions, concentrated in reconciliation and settlement. The 23.7% reduction in reconciliation expense and 18.2% reduction in settlement processing expense are consistent with the theoretical mechanism articulated by transaction cost economics: shared ledger state eliminates redundant verification and data entry, shifting coordination from hierarchical to network governance . These magnitudes align with the FRED-based study's estimate of approximately 15% structural reduction in back-office burden, though the present study finds somewhat larger effects, possibly because the sample includes banks with more mature implementations . The finding answers Research Question 1 by quantifying domain-specific savings and confirming their statistical significance.

Finding 2: CapEx reductions are real but smaller and more uncertain than OpEx reductions. The 14.1% CapEx reduction, while statistically significant, carries wider confidence intervals and lower predictive accuracy (84.7% versus 89.4%). This asymmetry is theoretically interpretable: CapEx savings arise from middleware consolidation and reduced integration complexity, but these benefits are partially offset by DLT infrastructure investment and the organizational costs of transition . The Bank of Canada's Project Samara finding that efficiency gains were "partially offset by increased system complexity" corroborates this interpretation .

Finding 3: Predictive accuracy of 89.4% is achievable with accessible bank-level predictors. The model's 89.4% accuracy in predicting above-versus-below median OpEx reduction demonstrates that DLT cost outcomes are not random but are systematically related to observable bank characteristics. The dominance of pre-implementation reconciliation intensity and syndicated loan volume as predictors indicates that DLT benefits are highest where manual reconciliation burden is greatest and where transaction volumes justify fixed implementation costs. This finding extends the existing literature by providing the first validated predictive framework for DLT cost estimation in US banking, answering Research Question 2.

Finding 4: Implementation barriers remain consequential. The finding that years since implementation is positively associated with realized savings ($\beta = 0.22$) suggests that benefits accrue gradually as organizational learning and process redesign accompany technical deployment. This is consistent with the Bank of Canada's caution that integration challenges and limited appetite for core infrastructure changes will slow adoption . The SWIFT initiative's explicit design choice to position its ledger as a "parallel track" rather than a replacement for existing infrastructure reflects awareness of these organizational constraints . This finding

addresses Research Question 3 by identifying implementation maturity as a moderator of realized benefits.

5.2 Implications

Academic implications. This study extends transaction cost economics to the domain of permissioned DLT by demonstrating that the technology's cost effects are domain-specific (reconciliation and settlement versus general overhead) and scale-contingent, consistent with the theory's emphasis on transaction frequency and asset specificity . It also contributes a methodological template for predictive modeling of institutional technology outcomes under conditions of limited implementation observations. The finding that organizational scale amplifies DLT benefits provides empirical support for Morningstar's thesis that technology adoption accelerates consolidation in banking .

Practical implications for bank administrators. Administrators should prioritize DLT investment evaluation based on two metrics: (1) pre-implementation reconciliation expense as a percentage of total operating expense, and (2) annual syndicated loan or cross-border settlement volume. Banks with reconciliation expense exceeding 8% of OpEx and transaction volumes above $50 billion annually are positioned to realize the full modeled savings. Expected lead time from implementation to realized savings is 24–36 months, with approximately 60% of projected OpEx benefits materializing by month 30. Administrators should not expect CapEx savings to offset implementation costs within the first two years.

For policymakers. The FDIC's forthcoming guidance on tokenized deposits should account for the finding that OpEx benefits are concentrated in reconciliation and settlement, suggesting that regulatory attention should focus on ensuring that tokenized deposit networks maintain appropriate netting and reconciliation standards rather than imposing uniform requirements across all DLT use cases . State supervisors' request for clarity on recordkeeping and reconciliation requirements is directly relevant to the domains where savings are largest .

5.3 Limitations

1. **Sample size and generalizability.** The 23 implementing banks, while representing a substantial share of US banking assets, are disproportionately large institutions. Findings may not generalize to community banks or to non-US banking systems with different regulatory architectures.
2. **Simulated CapEx components.** Middleware and integration expenditure data are estimated rather than directly observed, introducing measurement uncertainty into CapEx findings. Sensitivity analysis indicates that CapEx results are robust to ±20% variation in simulated values, but the precision of CapEx estimates is lower than that of OpEx estimates.

3. **Assumption of historical pattern stability.** The prospective simulation assumes that cost relationships estimated from 2016–2024 data will persist through 2029. Technological change, regulatory shifts, or macroeconomic disruptions could alter these relationships.
4. **Regulatory uncertainty as exogenous constraint.** The model treats regulatory uncertainty as a fixed implementation barrier rather than modeling its resolution probabilistically. If FDIC guidance on tokenized deposits is issued favorably, adoption rates and realized savings may exceed model projections .

5.4 Future Research Directions

1. Extension of the predictive framework to community banks ($1–10 billion in assets), where DLT consortium models rather than bilateral implementations may alter the cost structure.
2. Longitudinal analysis of administrator decision-making under DLT investment uncertainty, employing prospect theory to explain adoption timing heterogeneity.
3. Comparative analysis of permissioned DLT versus alternative process automation technologies (RPA, AI-based reconciliation) to isolate DLT-specific effects from general digital modernization.
4. Analysis of revenue-side effects, including the potential for tokenized deposit networks to enable new fee-based services that offset implementation costs.

6. Conclusion

This study provides empirical evidence that permissioned distributed ledger technology implementation in US commercial banking produces statistically significant reductions in both operational and capital expenditures, with OpEx reductions of 23.7% in reconciliation and 18.2% in settlement, and CapEx reductions of 14.1% over a five-year horizon. The predictive framework achieves 89.4% accuracy in classifying banks that realize above-median operational savings, establishing that DLT cost outcomes are systematically predictable from observable organizational characteristics. The main contribution is a replicable estimation model that bank administrators can employ ex ante to evaluate DLT investment proposals using institution-specific parameters rather than vendor assertions. For practitioners, the actionable takeaway is that DLT investment is most financially attractive for banks with high pre-implementation reconciliation burden and substantial transaction volumes in settlement-intensive business lines. As regulatory clarity on tokenized deposits advances and consortium infrastructure matures, the realized savings documented in this study are likely to diffuse more broadly across the banking

sector, but the pace of that diffusion will depend as much on organizational learning and regulatory enablement as on the technical capabilities of the technology itself.
