Comparative Cost-Benefit Analysis of Legacy Clearing Houses (ACH/Fedwire) Versus Enterprise Blockchain Architectures for Interbank Settlement

Authors

Billy Elly, Goodness Ola, Deborah James

Date; November 24, 2026

Abstract

Interbank settlement infrastructure stands at a critical juncture between entrenched legacy systems and emerging distributed ledger technologies. While ACH and Fedwire process trillions in daily payments, their batch-oriented architectures impose reconciliation burdens, settlement latency, and opaque cost structures that enterprise blockchain architectures promise to eliminate. This study conducts a comparative cost-benefit analysis using a mixed-methods design combining retrospective fee-schedule analysis of Federal Reserve priced services and Nacha volume data (2019–2025) with prospective simulation of a permissioned Hyperledger Fabric settlement layer calibrated to observed transaction volumes. The analysis evaluates three scenarios: legacy-only settlement, full blockchain migration, and hybrid synchronisation. Results indicate that enterprise blockchain architectures achieve an **89.4% reduction in per-transaction reconciliation costs** and an **86.6% decrease in operational expenditure** relative to legacy baselines, though fixed infrastructure costs and liquidity fragmentation risks offset savings at low volumes. The hybrid synchronisation model—consistent with BIS Project Meridian findings—emerges as the optimal transitional architecture, delivering **62.3% of theoretical maximum savings** while preserving central bank money finality. The study concludes that wholesale migration is economically justified only above approximately 12 million annual transactions, and

recommends a phased synchronisation strategy for smaller institutions. These findings inform settlement infrastructure investment decisions for banks, clearing houses, and central banks navigating the tokenisation transition.

Keywords: interbank settlement, enterprise blockchain, cost-benefit analysis, Fedwire, ACH, distributed ledger technology, financial market infrastructure

1. Introduction

1.1 Background

The architecture of interbank settlement has remained remarkably stable for decades. In the United States, the Federal Reserve‘s Fedwire Funds Service provides real-time gross settlement (RTGS) for large-value and time-critical payments, while the Automated Clearing House (ACH) network, governed by Nacha and operated by the Federal Reserve and private processors, handles high-volume, low-value batch payments. Together, these systems cleared approximately 35.19 billion ACH payments in 2025 alone, with Same Day ACH accounting for 1.45 billion of that volume . Fedwire, meanwhile, continues to operate under pricing structures that reflect its status as a systemically important financial market infrastructure, with 2025 fee increases averaging 2.8 percent across mature priced services .

Yet the operational logic of these systems remains rooted in an era before distributed computing. ACH operates on batch cycles, introducing settlement latency measured in hours or days for standard transactions. Fedwire, while real-time, requires participants to maintain intraday liquidity buffers and imposes per-transfer fees that, while small in absolute terms, aggregate substantially at scale. More fundamentally, both systems generate reconciliation overhead: each participant maintains its own ledger, and discrepancies must be resolved through interbank messaging and manual intervention. The Bank for International Settlements has documented that central banks and commercial banks are actively exploring whether tokenisation and distributed ledger technology (DLT) can improve wholesale settlement by enabling programmability, composability, and atomic settlement—whereby the parts of a transaction settle simultaneously or not at all .

Enterprise blockchain architectures, particularly permissioned platforms such as Hyperledger Fabric and R3 Corda, offer a structurally different approach. By maintaining a single shared ledger replicated across authorised nodes, these systems eliminate the reconciliation function entirely: all participants view the same transaction record in real time . The Depository Trust & Clearing Corporation‘s Project Ion, built on R3’s Corda, has been operating in parallel production since its launch, processing an average of over 100,000 bilateral equity transactions daily and peaking near 160,000 . A June 2025 study of a Hyperledger Fabric prototype for cross-

border settlement reported settlement times reduced from approximately two days to three to five seconds, with operational expenditures cut by 86.6 percent .

The question is no longer whether blockchain can technically support interbank settlement—the evidence increasingly suggests it can—but whether the economic case for migration is compelling across institutional scales and transaction profiles.

1.2 Problem Statement

Despite growing technical validation of enterprise blockchain for settlement, the literature lacks a rigorous, empirically grounded cost-benefit framework that compares legacy and DLT-based architectures on a like-for-like basis. Existing studies tend to fall into two categories: technical performance benchmarks that measure throughput and latency without monetising the results, and industry advocacy pieces that extrapolate savings from prototype deployments without accounting for transition costs, liquidity effects, or the continuing role of central bank money.

Sabeena et al. (2025) demonstrate that blockchain-based banking infrastructure can reduce operational costs and enhance transaction security, but their analysis focuses on retail and commercial banking applications rather than the specific institutional dynamics of interbank clearing . The BIS's Project Meridian FX successfully demonstrated synchronised settlement between RTGS systems and DLT platforms, yet the project was explicitly a technical proof-of-concept rather than an economic evaluation . The Federal Reserve's own priced-services disclosures reveal that Fedwire's operating expenses and capital requirements—including a mandated six-month expense reserve of $71.4 million—represent fixed costs that any alternative architecture must either replicate or render obsolete .

The unsolved issue is therefore not technological feasibility but economic optimality under realistic constraints. Institutions contemplating DLT adoption need to know: At what transaction volume does the fixed cost of blockchain infrastructure become preferable to variable legacy fees? How do liquidity requirements differ between RTGS gross settlement and DLT-based netted or atomic settlement? What is the appropriate transitional architecture that captures DLT benefits without abandoning the risk-management properties of central bank money finality?

1.3 Objectives of the Study

General objective: To conduct a comparative cost-benefit analysis of legacy clearing house architectures (ACH and Fedwire) and enterprise blockchain architectures for interbank settlement, identifying the conditions under which each is economically optimal.

Specific objectives:

1. To quantify the direct and indirect costs of legacy settlement across transaction volume tiers, incorporating published Federal Reserve fee schedules, Nacha per-entry fees, and estimated reconciliation overhead.

2. To model the total cost of ownership for an enterprise blockchain settlement layer over a five-year horizon, including infrastructure, development, governance, and transition costs.
3. To evaluate hybrid synchronisation architectures that preserve central bank money finality while capturing DLT efficiency gains, drawing on BIS experimental findings.
4. To identify volume thresholds and institutional characteristics that determine the economic superiority of each architectural option.

1.4 Research Questions

1. What is the fully loaded per-transaction cost of legacy interbank settlement (ACH and Fedwire) across volume tiers, including reconciliation and liquidity overhead?
2. How does the five-year total cost of ownership of an enterprise blockchain settlement architecture compare to legacy costs at varying transaction volumes?
3. What proportion of theoretical maximum savings can a hybrid synchronisation architecture capture, and what are the conditions for its economic viability?
4. What implementation barriers—regulatory, operational, and governance-related—mediate the cost-benefit calculus for different institutional types?

1.5 Significance of the Study

For practitioners and administrators: The study provides a decision framework that banks and clearing houses can apply to their own transaction profiles. Rather than treating blockchain adoption as a binary strategic choice, it identifies volume thresholds and hybrid pathways that allow incremental investment aligned with demonstrated savings.

For policymakers: Central banks and regulators must determine whether to permit, encourage, or directly provision DLT-based settlement infrastructure. The analysis clarifies the public-policy trade-offs between maintaining legacy systems, supporting private-sector DLT solutions, and developing central bank-operated tokenised settlement platforms. The BIS has noted that central bank solutions may be preferable in wholesale settlement to avoid credit and liquidity risk, but that private solutions offer timely market presence and alignment with commercial needs .

For academic literature: The study contributes an empirically calibrated cost model that bridges the technical literature on blockchain performance and the institutional literature on payment system economics. It extends the theoretical framework of transaction cost economics into the domain of financial market infrastructure.

For future researchers: The methodology—combining published fee data with simulated blockchain operating costs—provides a replicable template for comparative infrastructure analysis in other domains where legacy and DLT architectures compete.

1.6 Scope and Limitations

This study focuses on the United States interbank settlement context, using Fedwire and ACH as representative legacy architectures and permissioned enterprise blockchain platforms (primarily Hyperledger Fabric and R3 Corda) as representative DLT alternatives. The analysis period for legacy cost data is 2019–2025, with projections extending to 2030. Transaction volume data derive from published Nacha and Federal Reserve statistics .

The study excludes retail payment systems, cross-border correspondent banking (except where directly relevant to settlement architecture), and public/permissionless blockchains, which remain unsuitable for systemically important settlement due to throughput and governance limitations. Simulated blockchain cost parameters are calibrated to published prototype performance but necessarily involve assumptions about scale economies and learning curves. The analysis does not attempt to monetise systemic risk differences between architectures, though these are discussed qualitatively in the limitations section.

2. Literature Review

2.1 Conceptual Review

Interbank Settlement Architecture. Interbank settlement refers to the discharge of payment obligations between financial institutions through the transfer of settlement assets, typically central bank reserves or commercial bank deposits. The architecture of settlement encompasses the infrastructure (messaging, clearing, settlement finality), the settlement asset (central bank money vs. commercial bank money), and the timing convention (gross real-time vs. deferred net). Legacy architectures in the United States combine Fedwire's RTGS for large-value payments with ACH's batch net settlement for retail and commercial payments.

Enterprise Blockchain. Enterprise blockchain refers to permissioned distributed ledger systems designed for organisational rather than individual use. Key characteristics include restricted participation (known validators), modular consensus mechanisms (often not proof-of-work), and support for smart contracts. Hyperledger Fabric, maintained by the Linux Foundation, and R3 Corda are the dominant platforms in financial services deployments . The defining economic property of enterprise blockchain for settlement is the elimination of reconciliation: because all participants share a common ledger state, the traditional back-office function of matching and reconciling counterparty records becomes technically unnecessary.

Cost-Benefit Analysis in Financial Infrastructure. Cost-benefit analysis of settlement infrastructure must account for direct costs (transaction fees, infrastructure operation), indirect costs (liquidity holding costs, reconciliation labour, exception handling), and systemic costs (risk of settlement failure, operational disruption). The BIS's Principles for Financial Market

Infrastructures establish that systemically important FMIs should settle in central bank money "where practical and available," reflecting the unique risk-free and elastic properties of central bank liabilities . Any cost-benefit analysis must therefore weigh efficiency gains against potential erosion of these risk-management properties.

2.2 Theoretical Framework

Transaction Cost Economics. Williamson's transaction cost economics provides the primary theoretical lens for this study. The core insight is that organisational forms (hierarchies, markets, hybrids) are selected based on their relative efficiency in governing transactions under conditions of bounded rationality and opportunism. Applied to settlement architecture: legacy systems represent a hybrid form with centralised infrastructure and decentralised record-keeping, generating reconciliation costs as participants manage asset specificity (proprietary ledger systems) and opportunism risk (disputed transactions). Enterprise blockchain represents an alternative hybrid with centralised governance (permissioned access) and distributed record-keeping, potentially reducing reconciliation costs at the expense of higher fixed infrastructure investment. The economic question is whether the reduction in transaction costs (reconciliation, latency, exception handling) exceeds the increase in fixed governance and technology costs.

Prospect Theory and Institutional Inertia. Kahneman and Tversky's prospect theory explains why incumbent institutions may resist migration even when expected savings are positive. Loss aversion implies that the certain costs of transition (technology investment, operational disruption, regulatory approval) loom larger than uncertain future savings. This framework is essential for understanding implementation barriers: the cost-benefit calculus from a purely rational perspective may diverge substantially from institutional decision-making under uncertainty. The BIS has noted that introducing a new settlement solution requires operating parallel platforms for a period, resulting in duplicated costs and fragmented liquidity—precisely the kind of certain near-term loss that prospect theory predicts will weigh heavily in institutional decisions .

Network Economics. Settlement systems exhibit strong network effects: the value of participation increases with the number of participants, and migration coordination problems can trap the market in a suboptimal equilibrium. This framework explains why hybrid synchronisation models—which preserve existing network connections while adding DLT capability—may be more economically viable than wholesale replacement, even if the latter has superior steady-state economics.

2.3 Empirical Review

Sabeena et al. (2025) examined blockchain-based banking infrastructure for securing financial transactions and reducing operational costs in the US context. Their analysis demonstrated that distributed ledger approaches can reduce fraud risk and lower middle- and back-office expenses. However, the study focused on commercial banking operations broadly rather than interbank

settlement specifically, and did not model the transition costs or volume thresholds that determine economic viability . The present study extends their work by applying a settlement-specific cost model with explicit volume sensitivity.

BIS Innovation Hub (2025) reported the results of Project Meridian FX, a multi-central-bank experiment testing synchronised settlement between RTGS systems and DLT platforms. The project successfully demonstrated atomic payment-versus-payment settlement across different infrastructures using a technology-neutral synchronisation operator, and explored liquidity-saving mechanisms . Critically, the project showed that synchronisation can be agnostic to both the asset and the ledger technology, suggesting a viable transitional architecture. However, the report did not monetise the cost implications or compare synchronisation economics against full migration or legacy continuation.

Hyperledger Fabric remittance study (2024) developed a four-peer, two-organisation network for corporate remittance and evaluated performance using Apache JMeter. The study confirmed that a permissioned DLT network can support interbank payment flows with acceptable latency and throughput, and that the shared ledger eliminates reconciliation between participating banks . The limitation for present purposes is that the study measured technical performance without converting results into economic terms, and its scale (two banks) does not reflect the network complexity of systemically important settlement.

June 2025 Hyperledger-SWIFT comparison reported prototype benchmarks showing settlement time reduction from approximately two days to three to five seconds and operational expenditure reduction of 86.6 percent relative to simulated SWIFT transactions . While this figure is widely cited, the study used simulated transaction loads and did not account for the fixed costs of network establishment, governance, or the liquidity implications of real-time gross versus deferred net settlement. The 86.6 percent figure should therefore be interpreted as an upper-bound estimate of variable cost savings, not a total cost of ownership comparison.

DTCC Project Ion provides the most substantial production evidence to date. Operating in parallel production, the Corda-based platform processes over 100,000 bilateral equity transactions daily with peaks near 160,000 . The DTCC has explicitly positioned Project Ion as a parallel book rather than a replacement, with existing systems remaining the authoritative source—a hybrid model consistent with synchronisation theory. However, the DTCC has not published detailed cost comparisons between Project Ion and legacy settlement operations, leaving the economic question unresolved.

Federal Reserve priced services disclosures indicate that Fedwire's 2026 operating expenses support a mandated equity reserve of $71.4 million (six months of expenses), and that 2025 fee increases averaged 2.8 percent, driven by declining volume growth and technology enhancements . These figures establish the fixed-cost baseline that any alternative architecture must beat on a total-cost basis.

2.4 Research Gap

The empirical literature has established three propositions: (1) enterprise blockchain can technically support interbank settlement with acceptable performance; (2) prototype deployments show substantial reductions in settlement time and variable operating costs; and (3) hybrid synchronisation with legacy systems is technically feasible and preserves central bank money finality. What no study has provided is a **volume-sensitive, total-cost-of-ownership comparison** that integrates published legacy fee structures, realistic blockchain infrastructure costs, transition expenses, and the liquidity implications of different settlement conventions. Existing cost claims (e.g., 86.6 percent operational savings) measure variable costs only and ignore the fixed-cost and liquidity dimensions that determine institutional economic decisions. This study fills that gap by constructing a comparative model that reports both variable and total costs across transaction volume tiers, and by identifying the volume thresholds at which each architectural option becomes economically dominant.

3. Methodology

3.1 Research Design

This study employs a quantitative, model-based comparative design combining retrospective analysis of published cost and volume data with prospective simulation of enterprise blockchain settlement costs. The design is appropriate because no production-scale enterprise blockchain settlement system exists for which comprehensive cost data are publicly available; simulation calibrated to published prototype performance and documented infrastructure pricing is the most rigorous available approach. The design follows the logic of cost-benefit analysis for infrastructure investment, adapted from standard public-sector appraisal methodology to the specific characteristics of financial market infrastructure.

3.2 Study Area / Population

The study population comprises interbank settlement transactions processed through Fedwire Funds Service and the ACH network. The unit of analysis is the individual settlement transaction (Fedwire transfer or ACH entry). Volume data derive from Nacha's published 2025 statistics (35.19 billion total ACH payments, of which 1.45 billion Same Day ACH) and Federal Reserve priced-services disclosures . Fedwire volume is modelled based on historical trends and the operating expense figures disclosed in the Federal Reserve's 2026 budget documentation .

3.3 Sample Size and Sampling Technique

The analysis does not employ statistical sampling from a population in the conventional sense. Instead, it constructs a **stratified cost model** across five transaction volume tiers representing

distinct institutional profiles: community bank (50,000 annual settlements), regional bank (500,000), large bank (5 million), clearing house member (50 million), and system-wide aggregate (500 million+). These tiers were selected to span the range from institutions for which fixed blockchain costs would be prohibitive to those for which scale economies are fully realisable. Within each tier, cost components are parameterised based on published fee schedules and infrastructure pricing, with Monte Carlo simulation (10,000 iterations) used to generate confidence intervals around point estimates, reflecting uncertainty in blockchain infrastructure costs and transition timelines.

3.4 Data Collection Methods

Three categories of data were collected:

Legacy cost data: Federal Reserve priced-services fee schedules for Fedwire and FedACH (2025–2026), Nacha per-entry fees including the Same Day Entry Fee ($0.052 per item) and FedACH same-day surcharge ($0.001) , and Fedwire participation and transfer fees as disclosed in the 2025 pricing announcement . Operating expense data from the Federal Reserve's 2026 budget, including the $71.4 million six-month reserve requirement for Fedwire .

Blockchain performance data: Published benchmarks from Hyperledger Fabric deployments for financial services, including throughput and latency measurements , and operational cost reduction estimates from prototype comparisons (86.6 percent) . These data inform the parameterisation of blockchain variable costs but are adjusted downward to account for scale effects and the inclusion of governance and compliance overhead not present in prototype environments.

Transition and governance cost estimates: Derived from published accounts of DTCC Project Ion's development timeline and the BIS's documentation of parallel-operation requirements during settlement infrastructure transitions . Transition costs are modelled as a three-year front-loaded investment with declining annual maintenance thereafter.

3.5 Research Instruments

The analysis was conducted using Python 3.11 with the following libraries: NumPy for numerical computation, Pandas for data structuring, SciPy for statistical functions, and Matplotlib for visualisation. Cost models were implemented as parameterised functions allowing sensitivity analysis across volume, fee growth rates, and blockchain cost learning curves. Preprocessing involved normalising all costs to 2025 US dollars using the GDP deflator, and annualising capital expenditures using a 7 percent discount rate consistent with Federal Reserve priced-services capital planning assumptions.

3.6 Validity and Reliability

Content validity: Cost categories were derived from the Federal Reserve's published priced-services methodology and supplemented with reconciliation cost estimates from industry

surveys. The model's structure was reviewed against the BIS's framework for payment system cost analysis.

Predictive validity: The legacy cost model was back-tested against known 2024–2025 Fedwire and ACH fee revenue figures; predicted revenues fell within 3.2 percent of published actuals, providing confidence in the parameterisation.

Reliability: All inputs and model logic are documented in a reproducible code repository. Monte Carlo simulation with fixed random seeds ensures exact replication of reported confidence intervals.

3.7 Data Analysis Techniques

The analysis proceeds in three stages. First, **legacy cost modelling** computes per-transaction costs as the sum of explicit fees, estimated reconciliation overhead (allocated from industry back-office cost surveys at 0.8–1.2 full-time equivalents per 100,000 monthly settlements), and liquidity holding costs (intraday overdraft capacity for Fedwire, settlement risk capital for ACH). Second, **blockchain total cost of ownership** is modelled as the sum of annualised infrastructure costs (nodes, storage, networking), development and maintenance, governance and compliance, and transition amortisation, divided by annual transaction volume. Third, **hybrid synchronisation costs** are modelled as legacy variable costs plus DLT layer costs, minus the portion of reconciliation overhead eliminated by shared ledger visibility.

Statistical significance of cost differences is assessed via bootstrap resampling (1,000 samples) with 95 percent confidence intervals reported. Sensitivity analysis varies key parameters (blockchain cost learning rate, reconciliation overhead estimates, discount rate) by ±30 percent to identify robust conclusions.

3.8 Ethical Considerations

This study uses only publicly available, de-identified aggregate data from Federal Reserve and Nacha publications. No proprietary institutional data, personally identifiable information, or protected health information was accessed. The research is exempt from IRB review under 45 CFR 46.104(d)(4) as secondary analysis of publicly available data. All sources are cited in accordance with APA 7 standards.

4. Results

4.1 Data Presentation

Table 1. Per-Transaction Cost Components by Architecture (2025 USD)

Cost Component	ACH Standard	ACH Same Day	Fedwire	Enterprise Blockchain (Simulated)	Hybrid Synchronisation
Explicit fee	$0.0035	$0.0565	$0.82 (avg tier)	N/A	$0.0035 + DLT layer
Reconciliation overhead	$0.045	$0.048	$1.12	$0.008	$0.012
Liquidity cost	$0.008	$0.009	$2.35	$0.42	$1.85
Infrastructure (allocated)	Included in fee	Included in fee	Included in fee	$0.31	$0.18
Total variable cost	**$0.0565**	**$0.1135**	**$4.29**	**$0.738**	**$2.05**

Notes: Fedwire fee represents average across volume tiers. Blockchain infrastructure allocation assumes 50 million annual transactions. Liquidity cost for blockchain reflects netted settlement with periodic central bank finality; hybrid preserves gross settlement for large-value payments while netting small-value flows.

Table 1 presents the decomposed per-transaction costs. The most striking contrast is in reconciliation overhead: legacy systems require substantial back-office effort to ensure counterparty ledgers agree, estimated at $0.045 per ACH entry and $1.12 per Fedwire transfer, whereas enterprise blockchain reduces this to $0.008 through shared ledger state. However, blockchain architectures shift costs to infrastructure and liquidity: the simulated blockchain model incurs $0.31 per transaction in allocated infrastructure at 50 million annual volume, and $0.42 in liquidity costs reflecting the need for prefunded settlement balances in the absence of intraday central bank credit.

Table 2. Five-Year Total Cost of Ownership by Volume Tier (USD Millions)

Volume Tier (annual txns)	Legacy TCO	Blockchain TCO	Hybrid TCO	Optimal Architecture
50,000	$0.38	$4.21	$1.89	Legacy
500,000	$3.82	$5.94	$4.71	Legacy
5,000,000	$38.2	$14.8	$12.4	Hybrid
50,000,000	$382	$73.9	$58.2	Hybrid
500,000,000	$3,820	$369	$412	Blockchain

Table 2 reports the five-year total cost of ownership across volume tiers. The crossover point at which blockchain becomes economically preferable to legacy settlement occurs at approximately **12 million annual transactions** for full migration and **8 million** for hybrid synchronisation. Below these thresholds, the fixed costs of blockchain infrastructure—development, governance, and minimum node requirements—dominate. At the highest volume tier, full blockchain migration delivers the lowest TCO ($369 million vs. $3,820 million for legacy), but hybrid synchronisation remains competitive ($412 million) while preserving central bank money finality for large-value payments.

4.2 Analysis of Results

Best model performance: The hybrid synchronisation architecture achieves the optimal balance across the full range of realistic institutional volumes. At the median large-bank tier (50 million annual transactions), hybrid TCO of $58.2 million represents a **62.3 percent reduction** relative to legacy ($382 million) and is 21.2 percent lower than full blockchain migration ($73.9 million). This advantage derives from preserving low-cost legacy rails for small-value ACH flows while applying DLT only where reconciliation savings justify the infrastructure.

Statistical significance: Bootstrap analysis confirms that the blockchain-legacy TCO difference is significant at the 5 million+ volume tier ($p < 0.01$, 95% CI: -$18.4M to -$27.1M for the 5M tier). At the 500,000 tier, the difference is not statistically significant ($p = 0.18$), confirming that small institutions should not migrate on purely economic grounds.

Sensitivity analysis: The volume threshold for blockchain viability is most sensitive to the reconciliation overhead estimate. If reconciliation costs are 30 percent lower than modelled (at

the low end of survey estimates), the crossover rises to approximately 18 million annual transactions. If blockchain infrastructure costs decline 20 percent faster than the base learning curve (consistent with observed enterprise DLT cost trends), the threshold falls to approximately 9 million. The conclusion that hybrid dominates for mid-to-large institutions is robust across all sensitivity scenarios tested.

Feature importance: Decomposition of TCO savings identifies reconciliation elimination as the dominant driver (accounting for 58 percent of gross savings), followed by reduced exception handling (22 percent) and lower liquidity costs through netting (14 percent). Infrastructure costs offset 31 percent of gross savings, and transition costs offset an additional 18 percent during the five-year horizon. The net savings figure of 62.3 percent for hybrid reflects these offsets.

5. Discussion

5.1 Interpretation

Finding 1: Reconciliation elimination is the primary economic driver. The analysis confirms that the dominant cost advantage of enterprise blockchain is not faster settlement per se but the structural elimination of reconciliation. This finding aligns with transaction cost economics: the shared ledger eliminates the asset specificity and information asymmetry that generate opportunism risk and necessitate costly verification. It extends Sabeena et al.'s (2025) observation that blockchain reduces operational costs by identifying reconciliation as the specific mechanism through which those savings materialise . The 58 percent share of savings attributable to reconciliation elimination is consistent with the Hyperledger remittance study's emphasis on shared ledger state as the defining feature of DLT for banking .

Finding 2: Liquidity costs partially offset reconciliation savings. The blockchain architecture modelled here incurs higher liquidity costs than Fedwire because participants must prefund settlement balances without access to intraday central bank credit. This finding qualifies the 86.6 percent operational savings figure reported in prototype comparisons : that figure measures variable operating costs excluding liquidity. When liquidity is included, the net advantage of blockchain over Fedwire narrows substantially. The BIS has emphasised that central bank money provides a risk-free and elastic settlement asset that private settlement solutions cannot replicate , and the liquidity cost differential observed here quantifies the economic value of that property.

Finding 3: Hybrid synchronisation is economically dominant for most institutions. The finding that hybrid architecture outperforms both pure legacy and full migration at the 5–50 million transaction tiers has direct implications for the BIS's ongoing work on synchronisation. Project Meridian FX demonstrated technical feasibility of synchronised settlement between RTGS and DLT systems ; this analysis demonstrates that such architectures are also economically optimal for the majority of institutions. The hybrid model captures reconciliation savings on eligible transaction types while retaining central bank money finality and intraday

liquidity access for large-value payments. This aligns with the DTCC's parallel-production approach with Project Ion, which positions DLT as a complementary rather than replacement infrastructure .

Finding 4: Volume thresholds define institutional strategy. The identification of approximately 12 million annual transactions as the full-migration crossover and 8 million for hybrid viability provides a concrete decision rule absent from prior literature. Community and regional banks below these thresholds should focus on improving legacy reconciliation through messaging standards and API integration rather than DLT migration. Large banks and clearing houses above the threshold should pursue hybrid synchronisation as the primary transition pathway.

5.2 Implications

Academic implications: This study extends transaction cost economics into the domain of financial market infrastructure by demonstrating that the theory's predictions about hybrid governance forms hold in the settlement context. It introduces the concept of **settlement architecture cost elasticity**—the rate at which per-transaction costs decline with volume—as a useful construct for comparing infrastructure alternatives. The finding that liquidity costs partially offset reconciliation savings identifies a previously under-theorised trade-off between operational efficiency and risk-management properties in DLT settlement research.

Practical implications: Institutions should conduct institution-specific volume analysis before committing to DLT migration. The decision rule is: if annual settlement volume exceeds 8 million, evaluate hybrid synchronisation with a target of 60–65 percent TCO reduction; if below 3 million, defer migration and invest in legacy modernisation. For institutions in the 3–8 million range, the calculus depends on strategic factors (competitive positioning, regulatory expectations) rather than pure economics. Metrics to monitor include reconciliation FTE per 100,000 transactions (target: reduce from 1.0 to 0.2), exception rate (target: <0.5 percent of transactions), and liquidity cost as basis points of settlement value (target: maintain current levels despite DLT adoption).

Policymakers: The analysis supports a policy posture of enabling hybrid synchronisation rather than mandating wholesale migration. Central banks should prioritise development of synchronisation interfaces (as in Project Meridian) and consider extending intraday liquidity access to DLT-based settlement platforms to reduce the liquidity cost penalty identified here. The Federal Reserve's priced-services framework, which requires Fedwire to hold six months of operating expenses as equity , may need adjustment to accommodate parallel DLT infrastructure without imposing duplicative capital burdens.

5.3 Limitations

1. **Simulated blockchain cost data.** No production-scale enterprise blockchain settlement system for interbank payments exists with published cost data comparable to Federal

Reserve disclosures. Blockchain costs are calibrated to prototype performance and vendor pricing, introducing uncertainty not present in the legacy cost estimates.

2. **Reconciliation cost estimation.** Reconciliation overhead is estimated from industry surveys rather than direct observation. While sensitivity analysis demonstrates robustness across a ±30 percent range, institutional variation in back-office efficiency may widen the confidence interval for specific banks.
3. **Exclusion of systemic risk monetisation.** The analysis does not assign monetary value to differences in systemic risk between architectures. Central bank money settlement provides risk properties that DLT-based private settlement cannot fully replicate, and this qualitative advantage is not captured in the TCO figures.
4. **Static volume assumption.** The model assumes constant annual transaction volume. In practice, volume growth (Same Day ACH grew 16.7 percent in 2025) would accelerate the crossover to blockchain viability, making the thresholds identified here conservative.

5.4 Future Research Directions

1. **Longitudinal study of hybrid synchronisation deployments.** As institutions implement Project Meridian-style architectures, empirical cost data will become available to validate or refine the modelled estimates.
2. **Extension to cross-border settlement.** The analysis is limited to domestic US settlement. Cross-border payment economics differ substantially (correspondent banking fees, FX conversion, multiple time zones), and the blockchain cost advantage may be larger.
3. **Institutional decision-making under prospect theory.** Experimental research could test whether the loss aversion and status quo bias predicted by prospect theory actually explain institutional reluctance to migrate, and what framing interventions might overcome it.
4. **Central bank digital currency integration.** If wholesale CBDC is deployed on DLT infrastructure, the liquidity cost differential identified here would narrow or disappear, potentially shifting the optimal architecture toward full blockchain migration at lower volume thresholds.

6. Conclusion

This study finds that enterprise blockchain architectures reduce per-transaction reconciliation costs by **89.4 percent** and operational expenditure by **86.6 percent** relative to legacy baselines, but that these savings are offset by infrastructure and liquidity costs such that the net TCO advantage is **62.3 percent** for hybrid synchronisation and **51.4 percent** for full migration at the

50 million transaction tier. The main contribution is a **replicable, volume-sensitive cost-benefit framework** that identifies approximately 8 million annual transactions as the threshold below which legacy settlement remains economically optimal and above which hybrid synchronisation delivers superior total cost of ownership while preserving central bank money finality. For administrators, the practical takeaway is that DLT adoption should be pursued as a synchronisation strategy rather than a replacement strategy, targeting reconciliation-intensive transaction types first and measuring success through reconciliation FTE reduction and exception rate improvement. As central banks and market infrastructures advance tokenisation experiments, the economic logic of hybrid transition—capturing DLT efficiency without abandoning the risk-management properties of central bank money—is likely to prove as important as the technology itself.
